Charles Nicolle Hospital, Tunis, Tunisia

Objective
We report a postnatally diagnosed case of sirenomelia monopus.

Methods
Case report.

Results
A 41-year-old primigravidia woman followed for a monochorionic twin pregnancy. No history of preexisting or gestational diabetes. No smoking, no drinking, no drugs consumption. Pregnancy was uneventful. First and second trimesters ultrasound showed no abnormalities. Routine third trimester ultrasound revealed one fetus with intrauterine growth restriction, oligohydramnios and was in breech presentation. Adequate evaluation of the fetal morphology and anomalies was difficult due to oligohydramnios. The twin died inutero at 28 of gestation. Delivery was by caesarian section at 31 weeks of gestation. APGAR's score was 8 and 10 at one and five minutes, respectively. Birth weight was 980g. Postnatal examination showed caudal dysgenesis with fusion of lower limbs, single leg with single foot and two toes in the lower extremity, imperforate anus, absence of a urinary meatus, ambiguous external genitalia, no dysmorphic craniofacial and no anomalies of the spine. Radiography showed single femur with absent tibia and fibula. The infant died on the first day of life.

Conclusion
Sirenomelia is associated with a poor prognosis. Diagnosis should be done early in the first trimester of pregnancy.
